# ON THE SUMS OF DIGITS OF FIBONACCI NUMBERS 

David C. Terr<br>Department of Mathematics, University of California at Berkeley, Berkeley, CA 94720

(Submitted December 1994)

## 1. INTRODUCTION

The problem of determining which integers $k$ are equal to the sum of the digits of $F_{k}$ was first brought to my attention at the Fibonacci Conference in Pullman, Washington, this summer (1994). Professor Dan Fielder presented this as an open problem, having obtained all solutions for $k \leq 2000$. There seemed to be fairly many solutions in base 10 , and it was not clear whether there were infinitely many. Shortly after hearing the problem, it occurred to me why there were so many solutions. If one assumes that the digits $F_{k}$ are independently uniformly randomly distributed, then one expects $S(k)$, the sum of the digits of $F_{k}$, to be approximately $\frac{9}{2} k \log _{10} \alpha$, where $\alpha=\frac{1}{2}(1+\sqrt{5}) \approx 1.61803$ is the golden mean. Since $\frac{9}{2} \log _{10} \alpha \approx 0.94044$, we expect $S(k) \approx$ $0.94044 k$. Since this is close to $k$, we expect many solutions to $S(k)=k$, at least for reasonably small $k$. However, as $k$ gets large, we expect $S(k) / k$ to deviate from 0.94044 by less and less. Thus, it appears that, for some integer $n_{0}$, the ratio $S(k) / k$ never gets as large as 1 for $k>n_{0}$, so $S(k)=k$ has no solutions for $k>n_{0}$, and thus has finitely many solutions. In this paper, I present two closely related probabilistic models to predict the number of solutions. More generally, they predict $N(b ; n)$, the number of solutions to $S(k ; b)=k$ for $k \leq n$, where $S(k ; b)$ is the sum of the digits of $F_{k}$ in base $b$ [thus, $S(k ; 10)=S(k)$ ]. Let $N(b)$ denote the total number of solutions in base $b$ [thus, $N(b ; n) \rightarrow N(b)$ as $n \rightarrow \infty$ ]. Both models predict finite values of $N(b)$ for each base $b$. In the simpler model, $N(10)$ is estimated to be $18.24 \pm 3.86$, compared with the actual value $N(10 ; 20000)=20$.

## 2. THE NAIVE MODEL

In this model I assume that the digits of $F_{k}$ are independently uniformly randomly distributed among $\{0,1, \ldots, b-1\}$ for each positive integer $k$ and each fixed base $b \geq 4$. [It is fairly easy to prove that the only solutions to $S(k ; b)=k$ are 0 and 1 when $b=2$ or 3 . The proof involves showing that, for all sufficiently large $k$, we have $(b-1)\left(1+\log _{b} F_{k}\right)<k$.] Now let $\alpha=\frac{1}{2}(1+\sqrt{5})$ and $\beta=\frac{1}{2}(1-\sqrt{5})$. Then

$$
F_{k}=\frac{\alpha^{k}-\beta^{k}}{\sqrt{5}}=\frac{\alpha^{k}}{\sqrt{5}}+o(1) \text { for } k \rightarrow \infty
$$

The number of digits of $F_{k}$ in base $b$ is approximately the base- $b$ logarithm of this number, $k \log _{b} \alpha-\log _{b} \sqrt{5} \approx k \log _{b} \alpha=k \gamma$, where $\gamma=\log _{b} \alpha$ and I neglect terms of order 1. In this model, the expected value of each digit of $F_{k}$ is $\frac{1}{2}(b-1)$ and the standard deviation (SD) is $\sqrt{\frac{1}{12}\left(b^{2}-1\right)}$ (see [2], pp. 80-86). Therefore, the expected value of $S(k ; b)$ is approximately $\bar{S}=$ $\frac{k}{2}(b-1) \gamma$ and the SD is approximately $\sigma=\sqrt{\frac{k}{12}\left(b^{2}-1\right) \gamma}$. Let $\mathscr{P}_{1}(k ; \ell)$ denote the probability that $\widetilde{S}(k ; b)=\ell$, where $\widetilde{S}(k ; b)$ is distributed as the sum $Y_{k, 1}+Y_{k, 2}+\cdots+Y_{k,[k \gamma]}$, the $Y_{k, j}$ being independent random variables, each uniformly distributed over $\{0,1, \ldots, b-1\}$. According to the
central limit theorem ([2], pp. 165-77), if $k$ is reasonably large, the probability distribution is approximately Gaussian, so

$$
\mathscr{P}_{1}(k ; \ell) \approx \frac{1}{\sigma \sqrt{2 \pi}} \exp \left[\frac{-(\bar{S}-\ell)^{2}}{2 \sigma^{2}}\right]=\sqrt{\frac{6}{k \pi \gamma\left(b^{2}-1\right)}} \exp \left[\frac{-6\left(k \gamma\left(\frac{b-1}{2}\right)-\ell\right)^{2}}{k \gamma\left(b^{2}-1\right)}\right]
$$

Let $\mathscr{P}_{1}(k)=\mathscr{P}_{1}(k ; k)$; this is the estimated percentage of Fibonacci numbers $F_{k}$ for $k^{\prime}$ near $k$ whose base- $b$ digits sum to the index $k^{\prime}$. We have $\mathscr{P}_{1}(k) \approx A e^{-B k} / \sqrt{k}$, where

$$
A=\sqrt{\frac{6}{\pi \gamma\left(b^{2}-1\right)}} \quad \text { and } \quad B=\frac{6\left(\gamma\left(\frac{b-1}{2}\right)-1\right)^{2}}{\gamma\left(b^{2}-1\right)}
$$

Incidentally, it is clear that the only solutions $k$ for which $F_{k}<b$ are those for which $F_{k}=k$, namely 0,1 , and possibly 5 (if $b>5$ ). We might as well put in these solutions by hand. Thus, in the model, we only calculate $\mathscr{P}_{1}(k)$ for $k$ for which $F_{k} \geq b$ and add $N_{0}$ to the final result upon summing the probabilities, where $N_{0}=3$ if $b>5$, otherwise $N_{0}=2$. Thus, our estimate for $N(b ; n)$ in this model is

$$
N_{1}(b ; n)=N_{0}+\sum_{\substack{k \leq n \\ F_{k} \geq b}} \mathscr{P}_{1}(k) \approx N_{0}+\sum_{\substack{k \leq n \\ F_{k} \geq b}} \frac{A e^{-B k}}{\sqrt{k}}
$$

and the standard deviation of this estimate is [assuming that the $S(k, b)$ are uncorrelated for different values of $k$ ]

$$
\Delta_{1}(b ; n)=\sqrt{\sum_{\substack{k \leq n \\ F_{k} \geq b}} \mathscr{P}_{1}(k)\left(1-\mathscr{P}_{1}(k)\right)} \approx \sqrt{\sum_{\substack{k \leq n \\ F_{k} \geq b}} \frac{A e^{-B k}\left(\sqrt{k}-A e^{-B k}\right)}{k}} .
$$

This model gives good results for some bases, but not all. The next model is an improvement which seems to yield accurate results for all bases.

## 3. THE IMPROVED MODEL

In this model, I still assume that the digits of $F_{n}$ are uniformly distributed over $\{0,1, \ldots, b-1\}$, but with one restriction, namely, their sum modulo $b-1$. It is well known that the sum of the base-10 digits of a number $a$ is congruent to $a \bmod 9$. In general, the same applies to the sum of the digits in base $b$ modulo $b-1$. Thus, we have the restriction $S(k ; b) \equiv F_{k}(\bmod b-1)$. In particular, $k$ cannot be a solution to $S(k ; b)=k$ unless $k \equiv F_{k}(\bmod b-1)$. This latter equation is not too difficult to solve. Upon solving it, we end up with a restriction of the form

$$
\begin{equation*}
k \bmod q \in S \tag{1}
\end{equation*}
$$

Here, $q=[b-1, p]$, where $p=\operatorname{per}(b-1)$ is the period of the Fibonacci sequence modulo $b-1$ and $S$ is a specified subset of $\{0,1, \ldots, q-1\}$. If $k$ does not satisfy the above condition, it need not be considered, since the sum of its digits cannot equal $F_{n}$. On the other hand, if $k$ does satisfy the condition, we know that the sum of its digits is congruent to $F_{n}$ modulo $b-1$. In the improved model, we take this restriction into account and otherwise assume a uniform random distribution
of digits in $F_{n}$. In analogy to $\widetilde{S}(k ; b)$, let $\hat{S}(k ; b)$ be distributed as the sum $Y_{k, 1}+\cdots+Y_{k,[k \gamma]}$, the $Y_{k, j}$ being random variables uniformly distributed over $0,1, \ldots, b-1$ and independent except for the restriction that $Y_{k, 1}+\cdots+Y_{k,[k]]} \equiv F_{k}(\bmod b-1)$. We now estimate the probability $\mathscr{P}_{2}(k)$ that $\hat{S}(k ; b)=k$ to be $b-1$ times our earlier estimate in the case where $k$ satisfies (1) and zero otherwise, i.e.,

$$
\mathscr{P}_{2}(k)= \begin{cases}(b-1) \mathscr{P}_{1}(k) & k \bmod q \in S, \\ 0 & k \bmod q \notin S .\end{cases}
$$

Thus, in this model, the expectation and SD of $N(b ; n)$ are approximately

$$
N_{2}(b ; n)=N_{0}+\sum_{\substack{k \leq n \\ F_{k} \geq b}} \mathscr{P}_{2}(k) \approx N_{0}+(b-1) \sum_{\substack{k \leq n \\ F k \geq b \\ k \bmod q \in S}} \frac{A e^{-B k}}{\sqrt{k}}
$$

and

$$
\Delta_{2}(b ; n)=\sqrt{\sum_{\substack{k \leq n \\ F_{k} \geq b}} \mathscr{P}_{2}(k)\left(1-\mathscr{P}_{2}(k)\right)} \approx \sqrt{(b-1) \sum_{\substack{k \leq n \\ F_{k} k b \\ k \bmod q \in S}} \frac{A e^{-B k}\left(\sqrt{k}-A e^{-B k}\right)}{k}} .
$$

As an example of how to calculate $S$, consider $b=8$. In this case, $p=\operatorname{per}(7)=16$ and $q=$ $[7,16]=112$. To determine $S$, we first tabulate $k \bmod 16$ and $F_{k} \bmod 7$ for each congruence class of $k$ mod 16. Next, below the line, we tabulate the unique solutions modulo 112 to the congruences $x \equiv k(\bmod 16)$ and $x \equiv F_{k}(\bmod 7)$. Since $(16,7)=1$, by the Chinese Remainder Theorem, each of these solutions exists and is unique.

| $k \bmod 16$ | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $F_{k} \bmod 7$ | 0 | 1 | 1 | 2 | 3 | 5 | 1 | 6 | 0 | 6 | 6 | 5 | 4 | 2 | 6 | 1 |
| $k \bmod 112$ | 0 | 1 | 50 | 51 | 52 | 5 | 22 | 55 | 56 | 41 | 90 | 75 | 60 | 93 | 62 | 15 |

Thus, $S=\{0,1,5,15,22,41,50,51,52,55,56,60,62,75,90,93\}$. Note that, in this example, the pair of congruences $k \equiv j(\bmod p)$ and $k \equiv F_{j} \bmod b-1$ has a solution $\bmod q$ for every integer $j \bmod$ $p$. This is because, in this example, $b-1=7$ and $p=16$ are coprime. In general, this is not the case. For example, for $b=10$, we get $p=24$, which is not coprime to $b-1=9$. Thus, if we constructed a similar table for $b=10$, we would expect to get some simultaneous congruences without solutions. This is in fact the case, i.e., the pair of congruences $k \equiv 2(\bmod 24)$ and $k \equiv F_{2}=1(\bmod 9)$ has no solutions. We expect only one-third (eight) of them to have a solution, since $(9,24)=3$. In fact, we do get eight. For $b=10$, we find $S=\{0,1,5,10,31,35,36,62\}$ and $q=72$.

One might wonder by about how much $N_{1}(k ; b)$ and $N_{2}(k ; b)$ differ. To first order, they differ by a multiplicative factor depending on $b$, i.e., $N_{2}(b ; n) \approx M(b) N_{1}(b ; n)$. Recall that in going from the first model to the second, we selected $s$ out of every $q$ congruence classes modulo $q$, where $s=\# S$. Also, we multiplied the corresponding probabilities by $b-1$. Thus, $M(b)=$ $(b-1) s / q$. For some bases, $M(b)=1$, so the predictions of both models are essentially the same. This is true in particular whenever $b-1$ and $p$ are coprime, and also in some other cases, like $b=10$. However, there are other bases for which $M(b) \neq 1$; in fact, the difference can be quite
large! For instance, for $b=11$, we find $p=q=60$ and $s=14$, hence $M(11)=10 \times 14 / 60=7 / 3$, which is greater than 2 . Thus, for $b=11$, the second model predicts over twice as many solutions to $S(k ; 11)=k$ as the first model. In this case, as we will see, the second model agrees well with the known data; the first does not.

## 4. COMPARISON OF MODELS WITH "EXPERIMENT"

Every good scientist knows that the best way to test a model or theory is to see how well its predictions agree with experimental data. In this case, my "experiment" was a computer program I wrote and ran on my Macintosh LCII to determine $S(k ; b)$ given $k \leq 20000$ and $b \leq 20$. Incidentally, it is not necessary to calculate the Fibonacci numbers directly, only to store the digits in an array. Also, only two Fibonacci arrays need to be stored at one time. Nevertheless, trying to compute for $k>20000$ presented memory problems, at least for the method I used. Still, this turned out to be sufficient for determining with high certainty all solutions to $S(k ; b)=k$ except for $b=11$.

Here I present all the solutions I found for $4 \leq b \leq 20$ and $k \leq n$.

| $b=4, n=1000$ : | 0 | 1 |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| $b=20, n=1000:$ | 0 | 1 | 5 | 21 | 22 |  |  |  |

Next, I tabulated $N_{1}(b ; n) \pm \Delta_{1}(b ; n), N_{2}(b ; n) \pm \Delta_{2}(b ; n), N(b ; n),\left(\frac{b-1}{2}\right) \log _{b} \alpha$, and $M(b)$ for the above pairs $(b, n)$. Note how $N(b ; n)$ increases as $\left(\frac{b-1}{2}\right) \log _{b} \alpha$ approaches 1 .

| $b$ | $n$ | $N_{1}(b ; n) \pm \Delta_{1}(b ; n)$ | $N_{2}(b ; n) \pm \Delta_{2}(b ; n)$ | $N(b ; n)$ | $\left(\frac{b-1}{2}\right) \log _{b} \alpha$ | $M(b)$ |
| ---: | ---: | :---: | :---: | ---: | :---: | ---: |
|  | 1000 | $2.25 \pm 0.49$ | $2.43 \pm 0.61$ | 2 | 0.52068 | 1.00 |
| 4 | 1000 | $2.67 \pm 0.79$ | $2.76 \pm 0.72$ | 2 | 0.59799 | 1.00 |
| 5 | 1000 | $4.17 \pm 1.05$ | $5.04 \pm 1.25$ | 6 | 0.67142 | 2.00 |
| 6 | 1000 | $5.10 \pm 1.41$ | $6.18 \pm 1.42$ | 7 | 0.74188 | 1.50 |
| 7 | 1000 | $6.61 \pm 1.85$ | $5.84 \pm 1.47$ | 5 | 0.80995 | 1.00 |
| 8 | 1000 | $9.40 \pm 2.48$ | $8.57 \pm 2.09$ | 7 | 0.87604 | 1.00 |
| 9 | 5000 | $18.24 \pm 3.86$ | $17.77 \pm 3.46$ | 20 | 0.94044 | 1.00 |
| 10 | 20000 | 18 | $180.95 \pm 12.82$ | 183 | 1.00340 | 2.33 |
| 11 | 20000 | $79.71 \pm 8.72$ | $17.01 \pm 3.28$ | 18 | 1.06510 | 1.00 |
| 12 | 20000 | $17.03 \pm 3.71$ | $15.73 \pm 3.08$ | 21 | 1.12566 | 2.00 |
| 13 | 5000 | $9.71 \pm 2.56$ | $8.22 \pm 1.62$ | 10 | 1.18522 | 1.00 |
| 14 | 3000 | $7.15 \pm 2.01$ | $4.70 \pm 1.19$ | 3 | 1.24387 | 1.00 |
| 15 | 2000 | $5.93 \pm 1.69$ | $7.16 \pm 1.62$ | 6 | 1.30170 | 2.00 |
| 16 | 2000 | $5.21 \pm 1.47$ | $3.94 \pm 0.90$ | 3 | 1.35877 | 1.00 |
| 17 | 1000 | $4.75 \pm 1.31$ | $4.69 \pm 1.06$ | 4 | 1.41515 | 1.00 |
| 18 | 1000 | $4.42 \pm 1.18$ | $4.12 \pm 0.95$ | 5 | 1.47088 | 1.50 |
| 19 | 1000 | $4.10 \pm 1.08$ | $4.54 \pm 0.97$ | 5 | 1.52601 | 1.00 |
| 20 | 1000 | $4.01 \pm 1.00$ |  |  |  |  |

As one can see, the first model does not make accurate predictions for each base. In particular, its predictions for bases 11 and 13 are off by roughly 12 and 4.5 standard deviations, respectively. On the other hand, the second model seems to agree well with the known data for each base. For 12 out of 17 bases, its predictions are correct within one SD, and all 17 predictions are correct within two SD's. (The largest deviation, found for $b=13$, is -1.71 SD's.) Furthermore, there does not seem to be a directional bias of the model. Eight out of 17 of the predicted values are too high; the other 9 are too low. Thus, the second model looks good.

## 5. PREDICTING THE UNKNOWN

With this in mind, we can use the second model to make predictions for which we are unable to calculate at present. In particular, we can estimate $N(11)$, the total number of solutions to $S(k ; 11)=k$ in base 11, as well as the value of the largest one. We can also estimate the probability that we missed some solutions in each of the other bases we looked at. For these bases, I was careful to calculate out to large enough $n$ so that these probabilities should be very small.

I calculated $N_{2}(11 ; n) \pm \Delta_{2}(11 ; n)$ for $200000 \leq n \leq 4000000$ in intervals of 200000. Here are the results:

| $n$ | $N_{2}(11 ; n) \pm \Delta_{2}(11 ; n)$ |
| ---: | :---: |
| 200000 | $490.38 \pm 21.70$ |
| 400000 | $595.89 \pm 24.00$ |
| 600000 | $641.02 \pm 24.93$ |
| 800000 | $662.32 \pm 25.35$ |
| 1000000 | $672.83 \pm 25.56$ |

As can be seen, the results converge rapidly for large $n$. Let $N^{\prime}(b ; n)$ denote the estimated number of solutions to $S(k ; b)=k$ for $k>n$. Then we have

$$
\begin{aligned}
N^{\prime}(b ; n)=\sum_{\substack{k>n \\
k \bmod q \in S}} \frac{A e^{-B k}}{\sqrt{k}} & \approx M(b) \sum_{k>n} \frac{A e^{-B k}}{\sqrt{k}} \approx \frac{M(b) A}{\sqrt{B}} \int_{B n}^{\infty} \frac{e^{-x} d x}{\sqrt{x}} \\
& \approx M(b) A \sqrt{\frac{\pi}{B}} \operatorname{erfc} \sqrt{B n} \approx \frac{M(b) A}{B \sqrt{n}} e^{-B n},
\end{aligned}
$$

where I make the change of variables $y=\sqrt{x}$ in the integral to get the error function term. In the last step, I use an asymptotic expansion of erfc [1].

I next tabulated $N^{\prime}(b ; n)$ for the pairs $(b, n)$ used, except for $b=11$, where I used $n=$ 4000000, the largest $n$ for which I have estimated $N(b ; n)$. Since $N^{\prime}$ is much less than 1 in each case, the values of $N^{\prime}$ listed are the approximate probabilities that there is a solution to $S(k ; b)=k$ for $k>n$. I also tabulated the corresponding values of $A, B$, and $M(b)$. Note that for every base less than 20 , except $11, N^{\prime}(b ; n)$ is less than $10^{-6}$; in fact, the sums of these entries is roughly $10^{-6}$. Thus, if this model is accurate, there is about one chance in a million that I have missed any solutions in these bases. Also, note that the table of estimates of $N_{2}(11 ; n)$ can be used to estimate the largest solution to $S(k ; 11)=k$.

Suppose one wishes to find $n$ such that there is a $50 \%$ chance that there are no solutions larger than $n$. According to Poisson statistics, this happens when the $N_{2}(11 ; n)=\ln 2 \approx 0.69$. By interpolating in the previous table, we see that this occurs when $n \approx 1.9 \times 10^{6}$; this is roughly the value we can expect for the largest solution. Calculating $S(k ; 11)$ for $k$ up to $2.8 \times 10^{6}$ yields a $96 \%$ probability of finding all the solutions, and going up to $4 \times 10^{6}$ yields a $99.9 \%$ probability of finding them all. Perhaps someone will do this calculation in the near future.

## ACKNOWLEDGMENTS

I would like to give special thanks to my advisor, H. W. Lenstra, Jr., for helping me with this paper. In particular, he made me aware of the need for congruence relations in finding solutions to $S(k ; b)=k$.
